

The integration of a reusable scramjet vehicle as one of the stages of a multi-stage space launch system has the potential to reduce the cost of small payload orbital launches. This paper determines the maximum payload to orbit trajectory of a multi-stage rocket-scramjet-rocket system. This trajectory is calculated by formulating the problem as an optimal control problem, then solving it using the pseudospectral method. The optimal trajectory for the scramjet stage is found to involve an initial decrease in dynamic pressure, followed by constant dynamic pressure flight, and finally a pull-up manoeuvre. This optimal trajectory results in a X% improvement in payload mass to orbit when compared to a constant dynamic pressure trajectory. Furthermore, the pull-up manoeuvre decreases the maximum dynamic pressure experienced by the final rocket stage by X%. The sensitivity of the trajectory is tested by varying the maximum allowable dynamic pressure, and the drag produced by the vehicle. A maximum dynamic pressure variation of $\pm 5\text{kPa}$ is shown to produce only a +X% and -X% variation in the payload mass to orbit. A drag increase of 10% is shown to produce a similar optimal trajectory shape, indicating that the solution is robust to variation in trajectory and vehicle aerodynamics.

Trajectory Design of a Rocket-Scramjet-Rocket

Multi-Stage Launch System

I. Introduction

Currently most small satellites co-manifest with a larger payload, leaving their launch schedule and trajectory at the mercy of the major payload. The demand for small satellite launches is increasing,¹ driving the development of cheap and efficient launch systems for independent launches of small satellites. A multi-stage launch system incorporating a scramjet second stage has been proposed as a dedicated small satellite launch vehicle.² Scramjets (supersonic combustion ramjets) are airbreathing engines that operate over Mach numbers in the hypersonic range.³ Scramjet engines are a primary candidate for powering the next generation of small payload launch vehicles, producing higher specific impulse (I_{sp}) than rockets within their operating range. Other benefits of scramjets include increased flexibility of launch windows and an increased range of mission capabilities.⁴ Scramjets can accelerate a launch vehicle without the need to carry oxidiser on board, providing mass savings compared to rocket-powered vehicles. The reduction of mass carried within the vehicle fuselage enables the integration of avionics and landing gear, allowing for the design of a reusable vehicle in the style of conventional aerospace vehicles. However, a launch system must contain three stages, the first stage capable of accelerating the scramjet vehicle to its operating speed and a final stage for placing the payload in orbit.

This paper presents a trajectory for a rocket-scramjet-rocket launch system, designed using optimal control methods. This paper utilises a rocket-scramjet-rocket multi-stage launch system that has been proposed at the Centre for Hypersonics at The University of Queensland.² The trajectory profile of multi-stage vehicles has typically been designed around the scramjet stage flying a constant dynamic pressure trajectory.^{5–7} A constant dynamic pressure trajectory follows the maximum dynamic pressure that the scramjet-powered vehicle is able to withstand structurally, ensuring maximum thrust production from the scramjet engines. Such a trajectory produces maximum acceleration from the scramjet stage but may not be optimal for the overall multi-stage system. A constant dynamic pressure trajectory releases the final stage into a high dynamic pressure environment, at a potentially suboptimal trajectory angle. This release point may result in suboptimal performance of the final stage rocket and the inclusion of unnecessary design constraints. Calculating a trajectory using optimal control methods allows for a trade-off between the efficiency of the stages, to produce a maximum payload trajectory that does not necessarily involve the scramjet stage flying at maximum dynamic pressure.

Launch vehicles utilising rocket and airbreathing propulsion within a single stage have previously been shown to fly at maximum dynamic pressure for the majority of airbreathing operation, followed by a pull-up before airbreathing engine cut-off.^{8–10} A pull-up produces an overall favourable trade-off by allowing for the airbreathing engines to be used to increase the altitude of the launch vehicle, with the downside of reducing the thrust of the airbreathing engine due to a lower mass flow rate into the engine. The increase in altitude

and trajectory angle produced by a pull-up manoeuvre results in the rocket engines being ignited at higher altitude, allowing the rocket to operate with reduced drag. A trajectory involving a pull-up has been shown to be the optimal trajectory for vehicles where the rocket engines are not ignited until circularization altitude^{8,9} as well as vehicles where the rocket engine is ignited immediately after airbreathing engine cut-off.¹⁰

For launch systems with airbreathing and rocket propulsion combined within a single stage, the pull-up manoeuvre is a simple trade-off between velocity and altitude. However, for the proposed scramjet-rocket multi-stage system, the scramjet stage and rocket stage are sequential and separate completely. The resultant change in mass and aerodynamic characteristics adds to the complexity of the trajectory analysis. For a robust multi-stage trajectory design there is a trade-off between: I. The high efficiency of the scramjet engines, II. The thrust produced by the scramjet engines, III. The potential thrust of the rocket engines, IV. The energy necessary to increase the altitude of the scramjet stage, V. The aerodynamic efficiency when performing the required direction change.

A pull-up manoeuvre has previously been identified as having potential advantages for multi-stage airbreathing-rocket systems.^{11–13} However, these pull-up manoeuvres were performed in order to decrease the dynamic pressure to the operable limit of the rocket stage,^{11,12} or were prescribed in a suboptimal trajectory with variation in dynamic pressure.¹³ The inherent complexity of a multi-stage system delivering payload to orbit necessitates an investigation into the optimal launch trajectory design.

This paper utilises optimal control theory to generate the optimal trajectory path for a rocket-scramjet-rocket multi-stage vehicle. Optimal control theory allows a trajectory to be optimised in its entirety and has been widely used in aerospace applications for computing trajectories when there is a global objective to be optimised, such as minimum fuel or maximum payload delivery.^{14–16} Optimal control is also extremely flexible, as the optimal control problem can be modified easily to investigate a range of trajectory objectives.¹⁷ Highly nonlinear control problems (such as a complex model of hypersonic flight) necessitate the use of direct methods such as direct single shooting, multiple shooting, or collocation. Direct methods discretise the problem, and solve the nonlinear programming problem that results.¹⁸ The pseudospectral collocation method of optimal control is utilised in this study due to its accuracy, efficiency, and radius of convergence when compared to other optimal control techniques.^{18,19}

The remainder of the paper is as follows: Section II presents the design characteristics of all three stages. Section III presents the aerodynamic modelling of the system. Section IV presents an overview of the optimal control theory used including the problem definition and a description of the pseudospectral method. Section V presents optimal trajectory results for all three stages, including results verifying the use of the pseudospectral method, optimal trajectory results for a range of maximum dynamic pressure conditions, and optimal trajectory results with variation in the vehicle's aerodynamic characteristics.

II. The SPARTAN System

The system to be optimised, shown in Figures 1 and 2, includes a rocket-powered first stage, a scramjet-powered second stage, and a rocket-powered third stage for payload delivery to heliosynchronous orbit. The SPARTAN system^{7,20,21} is utilised in this study as a representative model for future multi-stage access to space systems incorporating airbreathing second stages. The following section details the design characteristics of all three stages.

Figure 1. Model of the first stage rocket and scramjet vehicle.

Figure 2. Side view of all three stages including internal view.

II.A. The First Stage Rocket

The first stage rocket is required to deliver the second stage to near horizontal flight at Mach 5.1 flight conditions, after which it is discarded. To achieve this, the first stage rocket is modelled as a Falcon-1e first stage scaled down lengthwise to 9.5m, keeping the original diameter of 1.67m.²² The first stage is attached to the rear of the scramjet second stage and is powered by a single LOX-kerosene Merlin 1-C engine. This scaled first stage has a structural mass of 1356kg, determined by scaling down the structural mass of the Falcon-1. Engine mass is kept constant. The mass of the fuel in the first stage is scaled as part of the optimisation routine, as the dynamics of the vehicle, and its ability to reach a given separation point, are very closely coupled to the available fuel mass.

II.B. The Scramjet Accelerator

The Scramjet-Powered Accelerator for Reusable Technology Advancement (SPARTAN) is a scramjet-powered accelerator under development by the University of Queensland to be used as the second stage in a scramjet-rocket-powered system for delivering small payloads to heliosynchronous orbit.²¹ The SPARTAN is designed to be capable of flying back after separation to a designated airfield close to the launch site.

The SPARTAN has a fuselage diameter of 2.1m and a mass of 9819kg, including the third stage rocket. It has been sized to hold the third stage rocket within the fuselage to reduce aerodynamic drag, as shown in Figure 2. The SPARTAN has three fuel tanks, two cylindrical tanks housed below the third stage rocket, and one conical tank housed in the nose of the vehicle. These tanks have a total volume of 22.0m³, and a total LH2 storage capacity of 1562kg. The SPARTAN is powered by four scramjet engines located on the bottom portion of the fuselage, sized to a nominal capture width of 0.65m. These engines are based on the Rectangular-to-Elliptical Shape Transition (REST) scramjet engine design²³ with modified inlets to fit to a conical fuselage via a C-REST inlet configuration.²⁴ Previous studies have indicated that using the SPARTAN as part of a three stage access to space system can produce payload mass fractions that compare favourably with similarly sized rocket systems.^{7,21}

II.C. The Third Stage Rocket

Figure 3. Schematic of the third stage rocket.

The third stage rocket is initially housed within the SPARTAN fuselage, as shown in Figure 2. At the end of the SPARTAN acceleration the third stage rocket initiates a burn, and performs an altitude increasing manoeuvre to achieve orbit. At the end of the burn time the rocket is allowed to coast until reaching horizontal flight, at which point it must have an altitude of at least 160km to ensure that the rocket is in an exoatmospheric orbit. The orbit is circularised using a further short burn, after which the payload delivery to heliosynchronous orbit is completed using a Hohmann transfer. The payload-to-orbit is determined by calculating the fuel remaining at the end of the Hohmann transfer. This remaining fuel is taken to be the payload-to-orbit capability of the vehicle.

To achieve this manoeuvre, the third stage rocket (Figure 3) has a total length of 9m, diameter of 1.05m and a total initial mass of 3300kg. It is modelled to be powered by a SpaceX LOX-kerosene Kestrel engine,²² weighing 52kg. Previous studies used a LOX-LH2 upper stage based on the RL-10-3A engine.²¹ In this

study the pressure-fed Kestrel engine is being used rather than the pump-fed RL-10-3A to reduce the cost of the disposable third stage rocket. The third stage has a structural mass of 285.7kg, equivalent to a structural mass fraction of 0.09 (calculated without heat shield), similar to the Falcon-1 second stage.²² The in-atmosphere, high dynamic pressure separation of the rocket stage requires the use of a heat shield that envelopes the rocket stage. The heat shield is constructed from a Tungsten nose piece, a Carbon-Carbon cone, and a phenolic cork cylinder. The heat shield weighs 125.6kg in total, and is discarded when the rocket reaches a dynamic pressure of 10Pa (atmospheric heating is assumed to be negligible at this point).^{7,21}

III. Aerodynamics, Propulsion and Dynamic Modelling

Multiple preliminary analysis tools have been used to model the aerodynamics and propulsion of the stages of the SPARTAN system. These have been chosen based on appropriateness for the design and Mach number regime of each stage.

III.A. Aerodynamics

An aerodynamic database of the first stage stack is generated using CART3D,²⁵ a high-fidelity inviscid analysis CFD package with adjoint based mesh refinement. The CART3D package uses a Cartesian cut-cell approach²⁶ resulting in a mesh of cubes everywhere except at body-intersecting cells. CART3D has been used successfully in a variety of aerospace applications including hypersonic launch systems²⁷ and has shown good agreement when compared to experimental results.²⁸ For the simulation the vehicle geometry is created using Creo Parametric 3.0²⁹ and a body fitted triangular mesh is generated using Pointwise 18.0.³⁰

A pressure field for Mach 2, -1° angle of attack calculated using CART3D is shown in Figure 4. Figure

Figure 4. Normalised density contours of first stage flight, Mach 2, -1° angle of attack.

5 shows an example of the mesh produced by CART3D. This mesh extends out to 50 body lengths at the far-field boundaries. Figure 6 examines convergence parameters of the CFD solution; the functional, its adjoint-based correction and error estimate. The functional and corrected functional converge and error estimate decreases steadily as the mesh is refined, indicating mesh convergence.

Figure 5. Adaptive mesh generated close to vehicle by CART3D for Mach 2, -1° angle of attack flight conditions.

Figure 6. CART3D verification parameters of error estimate and C_d functional.

The aerodynamics of the SPARTAN second stage are simulated using a set of aerodynamic coefficients developed in HYPAERO.^{21,31} HYPAERO utilises longitudinal strip theory to solve the surface pressures acting on the vehicle and to provide aerodynamic coefficients over the operating range of Mach numbers, angle of attacks and flap deflection angles of the vehicle. Atmospheric properties are drawn from the U.S. Standard Atmosphere 1976.³²

The aerodynamics of the third stage rocket were determined using a database generated using Missile DATCOM,³³ a preliminary design tool for estimating the aerodynamic characteristics of missile configurations.

III.B. Propulsion

The first stage Merlin 1-C is modelled by scaling the sea level thrust using the standard rocket thrust equation;

$$T = T_{SL} + (P_{SL} - P_{atm})A_e, \quad (1)$$

where T_{SL} is the sea level thrust, A_e is the exit area of $0.55m^2$ and P_{SL} and P_{atm} are the atmospheric pressure at sea level, and at the current flight altitude respectively. The Merlin 1-C is throttled to a constant

85% of maximum thrust to enable the rocket to pitch easily, giving a sea level thrust of 472.5kN.²² The vacuum specific impulse is 304s.²²

The scramjet engine model used is based on the C-REST database,²¹ which provides data points of engine performance over inlet conditions within the operational range, at 50kPa dynamic pressure equivalent conditions. This data is interpolated for the given inlet conditions to calculate the exit conditions and the specific impulse produced by the engine. The thrust, T , is then obtained by inclusion of the mass flow rate (\dot{m}) obtained via the inlet conditions, ie. $T = g_0 \dot{m} I_{sp}$. The C-REST engine is a fixed geometry engine, designed for operability at high Mach numbers. At lower Mach numbers, the addition of excessive fuel may cause the engine to choke and unstart, resulting in total loss of thrust. To avoid unstart, an equivalence ratio (ϕ) of less than 1 is necessary at low Mach numbers.

This third stage Kestrel engine has a vacuum specific impulse of 317s²² and a vacuum thrust of 30.7kN.²² The thrust is modelled using the standard rocket thrust equation to scale for atmospheric pressure;

$$T = T_{vac} - P_{atm} A_e. \quad (2)$$

III.C. Dynamic Model

The drag and lift produced by each stage of the vehicle are calculated using the standard definition of the aerodynamic coefficients:

$$F_d = \frac{1}{2} \rho c_d v^2 A, \quad (3)$$

$$F_L = \frac{1}{2} \rho c_L v^2 A. \quad (4)$$

The dynamics of all stages are calculated using an geodetic rotational reference frame, written in terms of the radius from centre of Earth r , longitude ξ , latitude ϕ , flight path angle γ , velocity v and heading angle ζ . The equations of motion are:³⁴

$$\dot{r} = v \sin \gamma \quad (5)$$

$$\dot{\xi} = \frac{v \cos \gamma \cos \zeta}{r \cos \phi} \quad (6)$$

$$\dot{\phi} = \frac{v \cos \gamma \sin \zeta}{r} \quad (7)$$

$$\dot{\gamma} = \frac{T \sin \alpha}{mv} + \left(\frac{v}{r} - \frac{\mu_E}{r^2 v} \right) \cos \gamma + \frac{L}{mv} + \cos \phi [2\omega_E \cos \zeta + \frac{\omega_E^2 r}{v} (\cos \phi \cos \gamma + \sin \phi \sin \gamma \sin \zeta)] \quad (8)$$

$$\dot{v} = \frac{T \cos \alpha}{m} - \frac{\mu_E}{r^2} \sin \gamma - \frac{D}{m} + \omega_E^2 r \cos \phi (\cos \phi \sin \gamma - \sin \phi \cos \gamma \sin \zeta) \quad (9)$$

$$\dot{\zeta} = -\frac{v}{r} \tan \phi \cos \gamma \cos \zeta + 2\omega_E \cos \phi \tan \gamma \sin \zeta - \frac{\omega_E^2 r}{v \cos \gamma} \sin \phi \cos \phi \cos \zeta - 2\omega_E \sin \phi \quad (10)$$

IV. Trajectory Optimisation

The three stage trajectory of the launch vehicle forms a complex optimisation problem, spanning a large range of velocity and altitude conditions with multiple changes in the vehicle dynamics and propulsion method. In order to simplify the problem, the three stages are calculated separately, and coupled together at the separation points $\mathbf{x}_1(t_{1,f})$ (first to second stage) and $\mathbf{x}_2(t_{2,f})$ (second to third stage). Together these problems have the form of a sequential decision making problem, where the global optimal solution can be determined using dynamic programming.³⁵

IV.A. Trajectory Planning as an Optimal Control Problem

The optimal trajectory for each stage is determined by calculating a control function $\mathbf{u}_a(t)$:

$$\min_{\mathbf{u}_a} C_a(\mathbf{x}_a(t_a), \mathbf{u}_a(t_a)) + C_{a \rightarrow b}(\mathbf{x}_a(t_{a,f})), \quad (11)$$

where a is the vehicle stage to be optimised and b is the following stage. $C_a(\mathbf{x}_a(t_a), \mathbf{u}_a(t_a))$ is a continuous cost function and $C_{a \rightarrow b}$ is a terminal cost, dependent on the state variables $\mathbf{x}_a(t_{a,f})$ at the end of the stage trajectory. This terminal cost is used in this study to connect the optimal control problem to the next stage, which allows for the overall trajectory to be designed using dynamic programming. The optimisation of Equation 11 subject to the vehicle dynamics has the form of a Bolza optimisation problem, where an objective function $J(\mathbf{x}, \mathbf{u}, t_f)$ is minimised,

$$J(\mathbf{x}(t), \mathbf{u}(t)) = \underbrace{M[\mathbf{x}(t_f)]}_{C_{a \rightarrow b}(\mathbf{x}_a(t_{a,f}))} + \underbrace{\int_{t_0}^{t_f} P[\mathbf{x}(t), \mathbf{u}(t)] dt}_{C_a(\mathbf{x}_a(t_a), \mathbf{u}_a(t_a))}, \quad t \in [t_0, t_f], \quad (12)$$

where M is the terminal cost function and P is the stage cost. The optimisation problem is subject to a set of state dynamics $\dot{\mathbf{x}}(t)$, which describe the behaviour of the system over the solution space:

$$\dot{\mathbf{x}}_a(t_a) = f[t_a, \mathbf{x}_a(t_a), \mathbf{u}_a(t_a)] \quad (13)$$

and constrained by the boundary conditions ψ of the system at the initial and final time points:

$$\psi_0[\mathbf{x}_a(t_{a,0}), t_{a,0}] = \mathbf{0}, \quad (14)$$

$$\psi_f[\mathbf{x}_a(t_{a,f}), t_{a,f}] = \mathbf{0}. \quad (15)$$

The dynamics are also subject to a set of inequality constraints defining the bounds of the problem:

$$\boldsymbol{\lambda}[\mathbf{x}_a(t_a), \mathbf{u}_a(t_a)] \leq \mathbf{0} \quad (16)$$

These bounds are chosen to span the possible operating ranges of the first stage and the SPARTAN to ensure an optimal solution. Solving this Bolza problem in a discrete simulation requires the use of numerical solution methods for which the pseudospectral method solver DIDO was chosen.³⁶

IV.A.1. The Pseudospectral Method for Optimal Control

The first and second stage trajectory solutions utilise the pseudospectral method, a form of direct spectral collocation.¹⁸ The pseudospectral method offers good convergence properties and relatively good computational speed while not compromising the accuracy of the optimal solution.³⁷ These properties make the pseudospectral method appropriate for optimising a hypersonic vehicle system. The pseudospectral method utilises a spectral collocation method approximation to convert the optimal control problem to nonlinear programming form. The use of the spectral method ensures that higher order terms of the dynamic equations are solved, and allows solution with high accuracy, even with relatively few collocation points.³⁸ The accuracy and validity of this method has been demonstrated for a variety of aerospace applications.^{14, 15, 39, 40}

IV.B. Optimisation Methodology

The three stages are considered as separate optimisation problems, which are coupled at the stage separation points. The first and second stages are coupled by a separation point which is determined by the optimal start point for the second stage trajectory, and used as an end condition on the first stage optimisation.

For the constant dynamic pressure case, the second and third stages are coupled by the end point of the second stage simulation, which is reached when the second stage has expended all of its fuel. The third stage trajectory is optimised for maximum payload from the end of the second stage trajectory.

For the maximum payload cases, the second and third stages are coupled *a priori* by running the third stage optimisation repeatedly for different separation altitudes, velocities and angles, and tabulating the results. The terminal cost for the second stage optimisation is generated from this table using interpolation. By setting the objective of the third stage optimisation to maximise payload mass, the coupled optimisation of the second stage in turn maximises payload mass over both stages. The coupling of the stage simulations means that the stage optimisations are performed backwards-in-time to design the complete trajectory; first the third stage is optimised for payload and tabulated over a range of altitudes, velocities and trajectory

angles, then the second stage is optimised for payload, and lastly the first stage is optimised for fuel mass to reach the optimal second stage start point.

IV.B.1. Third Stage Optimisation

The rocket stage trajectory is optimised for maximum payload, so that the second and third stages form a Bolza optimisation problem and maximise payload collectively. The cost function is configured to maximise payload at the end of the trajectory:

$$\min_{\mathbf{u}_3} C_{3 \rightarrow LEO}(\mathbf{x}_3(t_{3,f})) \quad (17)$$

where

$$C_{3 \rightarrow LEO}(\mathbf{x}_3(t_{3,f})) = -m_{payload}, \quad (18)$$

and $\mathbf{x}_3(t_{3,f})$ are the tabulated separation conditions of altitude, velocity and trajectory angle. A direct shooting optimisation is performed with ten angle of attack node points, interconnected by spline interpolation, and a variable end time point. These node points are spread evenly until the end time, after which the angle of attack is held at 0. A fixed amount of 2600kg of fuel is burned in this initial burn, so that burn time lasts until the rocket is in exoatmospheric flight. The maximum angle of attack is limited to 10° at 50kPa, and increased with altitude. The maximum allowable angle of attack is determined by keeping the maximum allowable normal force, F_N , constant. It is assumed that 10° angle of attack at 50kPa produces the maximum normal force allowable by the rocket structure. The payload mass is calculated after the Hohmann transfer to the desired orbit, by taking the remaining fuel to be the effective payload capacity. Sequential quadratic programming (SQP) is used to find the optimal solution, utilising MATLAB's *fmincon* solver.

Figure 7. Payload mass results with variation in rocket stage release point for $v = 2925\text{m/s}$, heading angle = 1.69 rad and latitude = -0.13 rad.

Tabulated optimal payload to orbit results for a 2925m/s third stage release velocity are shown in Figure 7. There is a distinct maxima in payload to orbit as release altitude increases. This is caused by the increased allowable angle of attack being offset by the reduction in lift due to reduced air density.

IV.B.2. Second Stage Optimisation - Constant Dynamic Pressure

The constant dynamic pressure case optimises the trajectory to minimise variation from the desired dynamic pressure. The trajectory is configured with a quadratic cost function centred around 50kPa dynamic pressure:

$$\min_{\mathbf{u}_2} C_2(\mathbf{x}_2(t_2), \mathbf{u}_2(t_2)) \quad (19)$$

where

$$C_2(\mathbf{x}_2(t_2), \mathbf{u}_2(t_2)) = \int_{t_{2,0}}^{t_{2,f}} \frac{(\mathbf{q} - 50 \times 10^3)^2 + 10^5}{10^5} \quad (20)$$

This quadratic function provides a smooth, continuous function to increase solver stability and ensure uniform dynamic pressure. Second-third stage separation occurs when the scramjet has expended all of its fuel. The third stage is then optimised for maximum payload from the calculated second-third stage separation point.

IV.B.3. Second Stage Optimisation - Optimal Payload

For the maximum payload optimisation, the second and third stages are considered using a dynamic programming approach. First, in order to increase the computational efficiency of the optimisation, optimal third stage payloads are tabulated over a 3 degree grid of separation conditions, $\mathbf{x}_2(t_{2,f})$, as described in Section

IV.B.1, providing the optimal payload for a range of velocity, altitude and trajectory angles at separation as shown in Figure 7. Then, the third stage payload interpolation is used as the terminal cost $C_{2 \rightarrow 3}(\mathbf{x}_2(t_{2,f}))$ for the calculation of the second stage trajectory optimisation, which optimises both the second and third stages by setting the cost function to maximise payload:

$$\min_{\mathbf{u}_2} C_2(\mathbf{x}_2(t_2), \mathbf{u}_2(t_2)) + C_{2 \rightarrow 3}(\mathbf{x}_2(t_{2,f})) \quad (21)$$

where

$$C_2(\mathbf{x}_2(t_2), \mathbf{u}_2(t_2)) = 0.01 \int_{t_{2,0}}^{t_{2,f}} \dot{m}_f dt \quad (22)$$

$$C_{2 \rightarrow 3}(\mathbf{x}_2(t_{2,f})) = -m_{payload}. \quad (23)$$

$C_2(\mathbf{x}_2(t_2), \mathbf{u}_2(t_2))$ is included to improve numerical stability and is chosen to have negligible effect on the resultant trajectory. This problem is solved using the pseudospectral method.⁴¹ The third stage is optimised for maximum payload from the calculated second-third stage separation point, as a check to ensure that the interpolation has provided an accurate payload-to-orbit result.

IV.B.4. First Stage Optimisation

After launch, the first stage flies vertically until 100m altitude, when a pitchover is initiated. After pitchover, the first stage is optimised for the minimum fuel mass necessary to reach the first-second stage separation conditions, $\mathbf{x}_1(t_{1,f})$, of 1520m/s velocity, and altitude and flight path angle determined by the second stage trajectory.

The separation velocity of 1520m/s corresponds to Mach 5.1 at 50kPa, the minimum operating point of the proposed scramjet.²¹ This velocity is held constant to allow for significant comparison to be made between cases. The minimum operating Mach number of the scramjet is chosen due to increasing velocity at first to second stage separation resulting in higher first stage fuel mass and lower scramjet stage specific impulse. Verification tests showed that a 5% increase in separation velocity results in a X% increase in first stage mass, and only a X% increase in payload to orbit. This indicates that increasing the fuel mass of the first stage is inefficient, as the increased stage separation velocity decreases the scramjet efficiency and provides diminishing returns in payload to orbit.

The altitude and flight path angle at first-second stage separation is defined by the optimised second stage. This approach is used on account of the selected first stage being able to reach the required range of altitudes and flight angles at 1520m/s with small fuel mass variations. Nevertheless small variation in fuel mass can have an important effect on the capabilities of the first stage, determining the velocity achievable at first to second stage separation, as well as the rate at which the rocket is able to pitch, and consequentially,

the altitude and flight path angle range of the first stage. The optimum (lowest fuel consumption) trajectory for the first stage stack that can reach first-second stage separation condition $\mathbf{x}_1(t_{1,f})$ is found by setting a cost function to minimise fuel mass:

$$\min_{\mathbf{u}_1} C_{1 \rightarrow 2}(\mathbf{x}_1(t_{1,f})) \quad (24)$$

where

$$C_{1 \rightarrow 2}(\mathbf{x}_1(t_{1,f})) = m_{fuel} \quad (25)$$

and the end point is fixed by the optimal second stage start conditions. The first stage is limited to -4° angle of attack to produce a conservative trajectory solution, within the capabilities of the vehicle. The optimal trajectory is solved for using the pseudospectral method.

V. Results and Discussion

The program LODESTAR (Launch Optimisation and Data Evaluation for Scramjet Trajectory Analysis Research) was developed to produce an optimal trajectory path for a rocket-scramjet-rocket launch vehicle. LODESTAR utilises DIDO,^{36,41} a proprietary pseudospectral method optimisation package, to optimise a trajectory towards a customisable objective (i.e. constant dynamic pressures or optimal payload mass). LODESTAR is used to investigate the suitability of a pseudospectral method approach to optimisation of scramjet-rocket trajectories and to develop optimal trajectory solutions. The following trajectories are developed:

1. : $q = 50\text{kPa}$ fixed SPARTAN trajectory
→ Verifies simulation and provides baseline trajectory.
2. : Trajectory optimised for payload-to-orbit, $q_{max} = 50\text{kPa}$
→ Demonstrates improved performance through coupled trajectory optimisation.
3. : Trajectory optimised for payload-to-orbit, $q_{max} = 45\text{kPa}$ & $q_{max} = 55\text{kPa}$

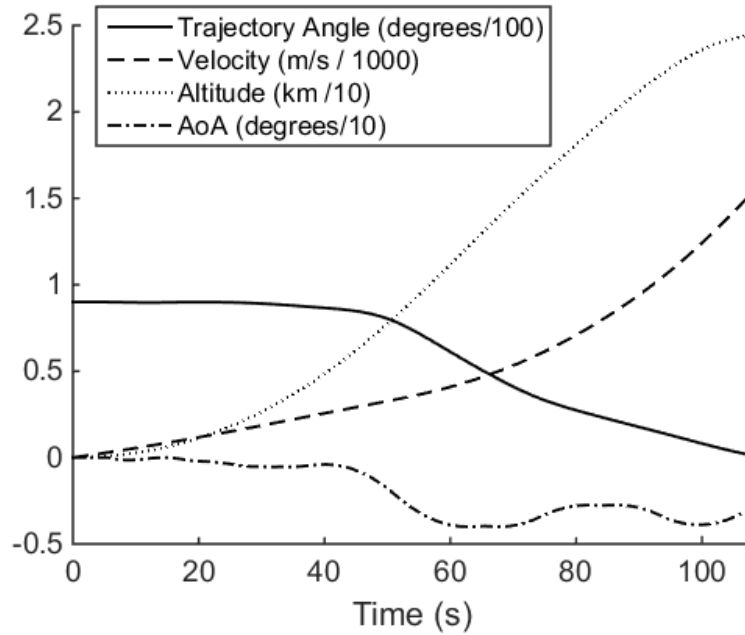

Figure 8. First stage trajectory, optimised for minimum fuel mass and a release point of 50kPa.

V.A. First Stage Evaluation - Constant $q=50\text{kPa}$ Second Stage

Figure 8 shows an example first stage trajectory, optimised for minimum mass, with end conditions of 24.4km altitude and 1.47° separation angle. These separation conditions correspond to the second stage separation conditions for a 50kPa constant dynamic pressure trajectory. The angle of attack is limited to $\pm X^\circ$ to produce a conservative estimate of vehicle capabilities.

The first stage flies a fixed vertical trajectory for X_s , after which a pitchover is initiated. After pitchover the angle of attack reduces gradually until X_s , at which point the angle of attack is reduced to $-X^\circ$, and then adjusted repeatedly in order to reach the desired end conditions. 24.4km altitude is reached after a total flight time of X_s . This trajectory shape is very similar for all first stage simulations cases.

V.B. Second Stage Evaluation

V.B.1. Fixed Dynamic Pressure Trajectory

Figure 9. Trajectory path of the 2nd stage SPARTAN vehicle flying at 50kPa constant dynamic pressure.

Figure 10. Trajectory data for 50kPa constant dynamic pressure trajectory.

Figure 11. Vehicle performance data for 50kPa constant dynamic pressure trajectory. Note: Flap deflection is positive down.

A constant dynamic pressure trajectory is produced as a baseline for comparison with a payload-optimised trajectory, and to verify that LODESTAR is able to optimise a complex airbreathing trajectory. Due to the clear objective of a constant dynamic pressure trajectory, any deviations from the target dynamic pressure are readily apparent, allowing the efficacy of the optimiser to be verified.

The constant dynamic pressure trajectory for the SPARTAN stage is shown in Figures 9, 10 and 11 with key results summarised in Table 1. These results show very close adherence to 50kPa dynamic pressure (maximum 0.04% deviation).

Flying a constant dynamic pressure requires a low trajectory angle. This results in a third stage release angle of X° to the horizontal. Over the Xs trajectory the Mach no. increases from 5.10 to X and the velocity from 1520m/s to Xm/s . The flap deflection shows an overall increase from -0.45° to 4.14° over the trajectory, trimming the vehicle. The net specific impulse ($I_{sp_{net}} = \frac{T-F_d}{\dot{m}_{fg}}$) generally decreases over the trajectory, as the efficiency of the scramjet engines decreases. However, at the beginning of the trajectory the equivalence ratio increases as the capture limitations are relaxed with increasing Mach number. This causes the net specific impulse to increase during the first Xs flight time.

Figure 20 shows the corresponding third stage atmospheric exit trajectory after release at 50kPa, evaluated as described in Section II.C. After atmospheric exit, this trajectory is followed by a Hohmann transfer to a heliosynchronous orbit, resulting in a total payload to orbit of Xkg .

V.B.2. Dynamic Pressure Limited Trajectory

Figure 12. Maximum payload trajectory path of the 2nd stage SPARTAN vehicle when limited to 50kPa dynamic pressure.

LODESTAR is configured to optimise the total payload mass to orbit. A maximum dynamic pressure limit of 50kPa is applied to the optimisation process to allow direct comparison with the constant q trajectory and so that an equivalent vehicle can be used. This trajectory is limited to 0.05 radians (2.86°) maximum trajectory angle to capture a conservative estimate of vehicle capabilities, ie. a trajectory that is within the

Figure 13. Trajectory data for 50kPa dynamic pressure limited trajectory.

Figure 14. Vehicle performance data for 50kPa dynamic pressure limited trajectory. Note: Flap deflection is positive down.

accepted operating region of the SPARTAN.

The optimal trajectory shape for a $q = 50\text{kPa}$ limited, maximum payload to orbit trajectory is shown in Figures 12, 13 and 14 with key results summarised in Table 1. The equivalence ratio of the engine is less than 1 until X_s , causing the SPARTAN to fly under 50kPa in this region (to a minimum of $X_k\text{kPa}$) in order to raise equivalence ratio by flying in a higher temperature region. This increase in equivalence ratio results in a corresponding increase in net specific impulse. After the equivalence ratio increases to 1, the trajectory follows a constant dynamic pressure path at 50kPa until X_s at which point a pull-up manoeuvre is performed, gaining altitude until rocket stage release at X_s flight time. This trajectory is able to deliver $X\text{kg}$ of payload to heliocentric orbit, an increase of $X\%$ over the constant dynamic pressure result. The point at which the pull-up manoeuvre begins is the optimisation result that takes into account the best combination of velocity, altitude and release angle for scramjet stage performance and the release of the rocket stage. This pull-up indicates the region at which increasing altitude and release angle becomes more important than extracting maximum thrust from the scramjet (which is attained at high q and low flight angle at an equivalence ratio of 1). Flight in a lower dynamic pressure environment results in less thrust output from

the scramjet engines, as well as an increase in angle of attack and flap deflection angle to compensate for the additional lift required. Due to this, less overall acceleration is obtained compared to the constant dynamic pressure result. Separation occurs at a velocity of $X\text{m/s}$, a decrease of $X\text{m/s}$. However, at the same time separation altitude increases by $X\text{km}$ to $X\text{km}$, resulting in a decreased separation dynamic pressure of $X\text{kPa}$.

The scramjet stage pull-up assists the rocket in manoeuvring to exoatmospheric altitude by increasing the altitude and angle at separation by virtue of the increased L/d ratio and manoeuvrability of the scramjet vehicle. Even a small increase in release angle to X° significantly reduces the turning that is required by the rocket as evident from comparing Fig 20 and 21. Further benefits are the reduced time that the rocket must spend in a high dynamic pressure environment, and a decrease in the maximum dynamic pressure that the rocket stage experiences by $X\%$, as shown in Table 1, which could allow the structural mass and heat shielding necessary to achieve exoatmospheric flight to be decreased, enabling higher payload to orbit.

Compared to studies considering vehicles with a scramjet-rocket transition within a single stage^{9,10} the maximum payload to orbit trajectory of the multi-stage system shows a scramjet-rocket transition point at much lower altitudes. This lower transition point is a consequence of the stage separation creating an energy trade-off which does not occur in a single stage vehicle. Single stage vehicles must necessarily transport all components to exoatmosphere, and so utilise the scramjet engines until higher altitude to take advantage of their high efficiency. A multi-stage vehicle is able to separate the scramjet stage. This separation occurs when the performance benefits provided by the superior aerodynamics and engine efficiency of the scramjet stage are offset by the energy needed to lift the extra mass to higher altitude. The beneficial ability to separate the scramjet stage results in a lower altitude scramjet-rocket transition point when compared to single stage vehicle designs.

V.B.3. Dynamic Pressure Sensitivity

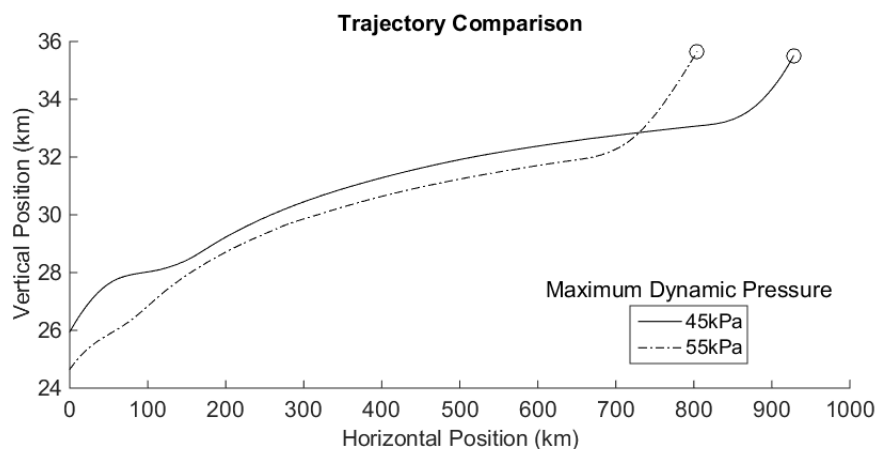

Figure 15. Comparison of 45kPa / 55kPa dynamic pressure limited trajectory paths for maximum payload to orbit.

Figure 16. Comparison of trajectory data for 45kPa / 55kPa dynamic pressure limited trajectories.

Figure 17. Comparison of vehicle performance data for 45kPa / 55kPa dynamic pressure limited trajectories.

To investigate the sensitivity of the vehicle to changes in q_{max} , the maximum dynamic pressure is varied to 45kPa and 55kPa and the flight trajectory optimised, with results shown in Figures 15, 16 and 17 and summarised in Table 1. The $\pm 10\%$ variation in maximum dynamic pressure has very little effect on the payload mass delivered to heliocentric orbit. Varying the maximum dynamic pressure by $\pm 5\text{kPa}$ from 50kPa causes a variation of only $+X\text{kg}(+X\%)$ or $-X\text{kg}(-X\%)$ in payload to orbit. Separation altitudes of $X\text{km}$ and $X\text{km}$ are reached for 45kPa and 55kPa limited cases respectively, with separation velocities of $X\text{m/s}$ and $X\text{m/s}$. The 45kPa limited case flies for $X\text{s}$, significantly longer than the 55kPa case which flies for $X\text{s}$. Both trajectories pull-up to similar altitudes, with relatively small variation in separation velocity ($-X\text{m/s}$ or $+X\text{m/s}$). This small variation in velocity is despite the increase in air density and decrease in angle of attack required for flight at 55kPa dynamic pressure, both of which increase the mass flow into the engine. Although the thrust output of the REST engines increases with dynamic pressure, so does the drag on the vehicle, and the net increase in performance is small.

Only small variation in optimal payload mass is observed, without modification of vehicle design to

account for the dynamic pressure limit. This indicates that designing and operating a vehicle at lower dynamic pressures may be preferable. Flying at a lower maximum dynamic pressure allows reduction of the structural weight and heat shielding of the vehicle. Additionally, flying at low dynamic pressure allows the third stage to be released into lower dynamic pressure, lessening the structural and heat shielding requirements of the third stage rocket. However, as the 45kPa limited case has a higher release altitude, a larger first stage fuel mass is required, though this increase in fuel mass is small. Between Xkm and Xkm (45kPa and 55kPa optimal start points) there is only a X % variation in required fuel mass. This small variation in first stage fuel consumption would easily be offset by a decrease in second stage structural mass.

V.B.4. Drag Sensitivity Analysis

Figure 18. Comparison of trajectory paths for 100% and 110% drag cases for a 50kPa dynamic pressure limited maximum payload trajectory.

Figure 19. Comparison of v and $I_{sp_{net}}$ for 100% and 110% drag cases for a 50kPa dynamic pressure limited maximum payload trajectory.

To investigate the effect of vehicle design and uncertainty in aerodynamic performance on the optimal trajectory the drag on the vehicle is increased by 10%, and an optimised trajectory calculated with dynamic pressure limited to 50kpa. Selected results are compared to the 100% drag result in Figures 18 and 19.

These results show that when drag is increased (ie. L/d is decreased) the optimal trajectory shape is similar to the base-line case, though the high drag second stage follows a slightly slower and hence lower flight path, with a lower stage transition point. The similar flight path shape of the high drag case suggests that sacrificing velocity to increase separation altitude in a pull-up manoeuvre is optimal for multiple vehicle designs. Although the lower transition point indicates that the rocket is favoured at an earlier point in the climb manoeuvre, due to the decreased aerodynamic efficiency of the scramjet vehicle. The net result is a lower payload-to-orbit of Xkg (a decrease of X %).

V.C. Third Stage Evaluation

Third stage trajectories are shown in Figures 20 and 21. These trajectories correspond to third stage release points at the end of a constant dynamic pressure trajectory (as shown in Section V.B.1) and an optimised 50kPa limited trajectory (as shown in Section V.B.2).

These third stage trajectories show a pull-up to high altitude before the circularisation burn is performed. However, the initial part of the trajectories involves a decrease in trajectory angle prior to the pull-up. At this stage, the rocket does not have the lift required to sustain increasing altitude. An initial decrease in the trajectory angle of the rocket allows the third stage to accelerate in-atmosphere, increasing the lift of the rocket and enabling it to reach exoatmospheric conditions. This drop in altitude is constrained so that the rocket cannot drop below the altitude of second-third stage separation, to keep the dynamic pressure reasonable and to produce a conservative trajectory estimate considering the manoeuvrability of the rocket.

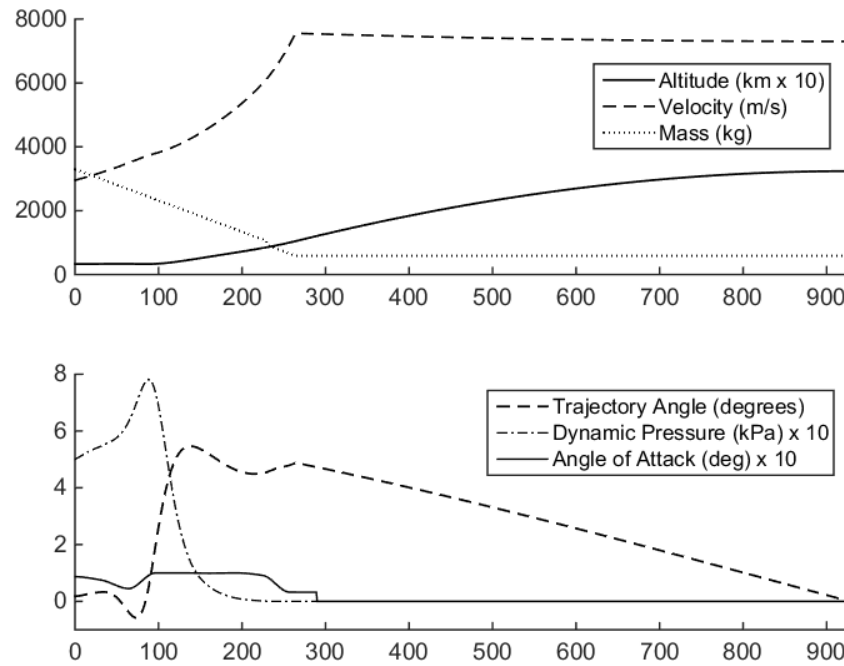

Figure 20. Third stage rocket trajectory simulated from the end of the 50kPa constant dynamic pressure SPARTAN trajectory.

Figure 21. Third stage rocket trajectory simulated from the end of the 50kPa dynamic pressure limited maximum payload SPARTAN trajectory.

VI. Conclusions

In this paper an optimal control program, LODESTAR, is used to design the trajectory of a rocket-scamjet-rocket multi-stage system. This system consists of a rocket-powered first stage, modelled on a scaled down LOX-kerosene Falcon-1; the SPARTAN, a scramjet accelerator being developed at the University of Queensland; and a LOX-kerosene rocket-powered third stage based on the Kestrel engine. Applied to full trajectory optimisation, LODESTAR is able to generate optimised trajectories that increased the payload to orbit of the multi-stage system.

Results indicate that the optimal scramjet flight path for a system transitioning between separate air-breathing and rocket-powered stages is to fly at lower than maximum dynamic pressure while equivalence ratio is less than 1, followed by constant dynamic pressure flight at maximum dynamic pressure, and finally a pull-up manoeuvre. The optimal flight path increases payload mass to heliocentric orbit by X kg (X%) compared to a constant dynamic pressure trajectory. The optimal pull-up manoeuvre trades off velocity (a decrease of X m/s) for altitude (an increase of X km). The pull up manoeuvre also limits third stage dynamic pressure to XkPa, a decrease of X% compared to a trajectory with no pull-up. This decrease in maximum dynamic pressure decreases the stress experienced by the rocket stage proportionally, as well as decreasing the heat flux into the rocket, both of which lead to significant benefits for the design of the rocket stage (which are not taken into account in this study). A decrease in structural stress allows for less internal reinforcement, and a decrease in heat flux allows for reduction of the heat shield size, potentially resulting in further increases in payload mass.

As part of a dynamic pressure sensitivity evaluation, the maximum dynamic pressure limit of the SPARTAN vehicle is varied by $\pm 5\text{kPa}$. This produces only a $+X\%$ and $-X\%$ variation on the payload mass delivered to orbit. This small variation in payload-to-orbit indicates that a scramjet-powered stage designed for operation at lower dynamic pressure may be advantageous. If efficient, low dynamic pressure scramjet engines are available, operating at lower dynamic pressure enables lighter vehicles due to reduced structural and thermal loads. This reduction in mass potentially leads to further performance improvements and operational benefits including increased payload to orbit and extended range.

To investigate the effect of changes in second stage vehicle properties, the drag of the scramjet is increased by 10% and the optimal trajectory evaluated. This resulted in a pull-up manoeuvre with a lower second-third stage transition point when compared to the original result, indicating that the rocket is favoured at an earlier point in the climb manoeuvre. This variation in the optimal trajectory is minor, indicating that the presented trajectory shape is robust with respect to changes in vehicle design and, by extension, changes in engine performance or vehicle aerodynamics. Thus re-optimisation of the trajectory while taking account of the new aerodynamic performance is a good approach to minimise impacts on the aggregate performance

of the system.

Overall this work provides new insight into the preferred operating ranges for scramjet vehicles incorporated in multi-stage to orbit systems.

Acknowledgments

The authors would like to thank Dawid Preller for his work on the SPARTAN vehicle which is integral to this study, and Joseph Chai for providing the CAD model of the SPARTAN.
